LPs in General Form

$$\min \quad c_1x_1 + \dots + c_nx_n$$

$$\text{s.t.} \quad L_i \leq a_{i,1}x_1 + \dots + a_{i,n}x_n \leq U_i \quad \text{for } i = 1, \dots, m$$

$$\ell_k \leq x_k \leq u_k \quad \text{for } k = 1, \dots, n$$

$\Leftrightarrow$

$$\min \quad c^T x$$

$$\text{s.t.} \quad L \leq Ax \leq U$$

$$\ell \leq x \leq u$$

where

- **lower bounds** L_i, ℓ_k may be $-\infty$ and **upper bounds** U_i, u_k may be $+\infty$,
- so constraints may be inequalities, ranged rows ($-\infty < L_i < U_i < +\infty$) or equations,
- and variables may be **free** ($-\infty = \ell_k \wedge u_k = +\infty$).
- The term **row** can refer to a constraint or a row vector $a_{i,*}$,
- the term **column** can refer to a variable or a column vector $a_{i,*}$ of the **constraint matrix** A .

Often, A is highly sparse, i.e., most $a_{i,k} = 0$. The other coefficients are called **nonzeros**.

Vertices = primal feasible basic solutions

This inequality-based form aligns well with the intuitive 3D visualization of the feasible region as a **full-dimensional polytope** (sometimes wrong, but nevertheless helpful).

Its **vertices** have a discrete representation as a set of n **linearly independent tight inequalities**.

In a simplex solver, this information is encoded for each row and column via the

$$\text{basis status} \in \begin{cases} \text{basic (not tight)} \\ \text{tight on lower bound} \\ \text{tight on upper bound} \\ \text{fixed at zero (also called free/superbasic)} \end{cases}$$

All in all, 4 possibilities = 2 bits per row and column needs $2(m + n)$ bits (less than the numerical solution).

Basic solutions in general

In general, any set of n linearly independent tight inequalities defines a unique solution, which can be computed by a **linear system of equations** $Bx = b$ with

- B an $n \times n$ submatrix of $\begin{pmatrix} A \\ I \end{pmatrix}$ corresponding to non-basic (tight) rows and columns,
- b the vector of bounds L_i, U_i, ℓ_k, u_k or 0 according to basis status.

Basic solutions in general

In general, any set of n linearly independent tight inequalities defines a unique solution, which can be computed by a **linear system of equations** $Bx = b$ with

- B an $n \times n$ submatrix of $\begin{pmatrix} A \\ I \end{pmatrix}$ corresponding to non-basic (tight) rows and columns,
- b the vector of bounds L_i, U_i, ℓ_k, u_k or 0 according to basis status.

In general, such a basis can be

1. **PRIMAL feasible** if $x = B^{-1}b$ satisfies all constraints
2. **OPTIMAL** if primal feasible and $c^T x$ minimal
3. **DEGENERATE** if primal feasible and $c^T x$ not unique
4. **REGULAR** if none of the above
5. **SINGULAR** if $\text{rank}(B) < n$ (error, possibly due to numerics)

Basic solutions in general

In general, any set of n linearly independent tight inequalities defines a unique solution, which can be computed by a **linear system of equations** $Bx = b$ with

- B an $n \times n$ submatrix of $\begin{pmatrix} A \\ I \end{pmatrix}$ corresponding to non-basic (tight) rows and columns,
- b the vector of bounds L_i, U_i, ℓ_k, u_k or 0 according to basis status.

In general, such a basis can be

1. **PRIMAL feasible** if $x = B^{-1}b$ satisfies all constraints
2. **OPTIMAL** if primal feasible and $c^T x$ minimal
3. **DUAL feasible** if ...?
4. **REGULAR** if none of the above
5. **SINGULAR** if $\text{rank}(B) < n$ (error, possibly due to numerics)

The dual LP: special case

First consider

$$\min c^T x \text{ s.t. } Ax \geq b, x \geq 0$$

Goal: get **lower bound** $c^T x \geq d$.

The dual LP: special case

First consider

$$\min c^T x \text{ s.t. } Ax \geq b, x \geq 0$$

Goal: get **lower bound** $c^T x \geq d$.

Idea: express objective direction c as **conic combination of constraints**

$$c = y^T A + r^T I \text{ with } y, r \geq 0$$

Why?

The dual LP: special case

First consider

$$\min c^T x \text{ s.t. } Ax \geq b, x \geq 0$$

Goal: get **lower bound** $c^T x \geq d$.

Idea: express objective direction c as **conic combination of constraints**

$$c = y^T A + r^T I \text{ with } y, r \geq 0$$

Why? This gives a valid lower bound a.k.a. the **weak duality theorem**:

$$c^T x = (y^T A + r^T I)x = y^T Ax + r^T x \geq y^T b + 0 := d$$

The **dual LP** computes the tightest bound:

$$\max b^T y \text{ s.t. } A^T y + r = c, y, r \geq 0.$$

The dual LP: general case

$$\begin{array}{ll}\min & c^T x \\ \text{s.t.} & L \leq Ax \leq U \\ & \ell \leq x \leq u\end{array}$$

 $\geq$

$$\begin{array}{ll}\max & L^T y^L - U^T y^U + \ell^T r^\ell - u^T r^u \\ \text{s.t.} & A^T(y^L - y^U) + (r^\ell - r^u) = c \\ & y^L, y^U, r^\ell, r^u \geq 0\end{array}$$

The dual LP: general case

$$\begin{array}{ll}\min & c^T x \\ \text{s.t.} & L \leq Ax \leq U \\ & \ell \leq x \leq u\end{array}$$

 $\geq$

$$\begin{array}{ll}\max & L^T y^L - U^T y^U + \ell^T r^\ell - u^T r^u \\ \text{s.t.} & A^T(y^L - y^U) + (r^\ell - r^u) = c \\ & y^L, y^U, r^\ell, r^u \geq 0\end{array}$$

Strong duality (“=”) holds if x and y, r are **complementary slack**, i.e.,

$$\begin{array}{ll} y_i^L > 0 \Rightarrow y_i^U = 0, (Ax)_i = L_i & r_k^\ell > 0 \Rightarrow r_k^u = 0, x_k = \ell_k \\ y_i^U > 0 \Rightarrow y_i^L = 0, (Ax)_i = U_i & r_k^u > 0 \Rightarrow r_k^\ell = 0, x_k = u_k \end{array}$$

because then $c^T x = (y^L - y^U)^T Ax + (r^\ell - r^u)^T x = \dots?$

The dual LP: general case

$$\begin{array}{ll}\min & c^T x \\ \text{s.t.} & L \leq Ax \leq U \\ & \ell \leq x \leq u\end{array}$$

 $\geq$

$$\begin{array}{ll}\max & L^T y^L - U^T y^U + \ell^T r^\ell - u^T r^u \\ \text{s.t.} & A^T(y^L - y^U) + (r^\ell - r^u) = c \\ & y^L, y^U, r^\ell, r^u \geq 0\end{array}$$

Strong duality (“=”) holds if x and y, r are **complementary slack**, i.e.,

$$\begin{array}{ll} y_i^L > 0 \Rightarrow y_i^U = 0, (Ax)_i = L_i & r_k^\ell > 0 \Rightarrow r_k^u = 0, x_k = \ell_k \\ y_i^U > 0 \Rightarrow y_i^L = 0, (Ax)_i = U_i & r_k^u > 0 \Rightarrow r_k^\ell = 0, x_k = u_k \end{array}$$

because then $c^T x = (y^L - y^U)^T Ax + (r^\ell - r^u)^T x = L^T y^L - U^T y^U + \ell^T r^\ell - u^T r^u$.

Note: Solvers return only one dual multiplier $y_i = y_i^L - y_i^U$ and $r_k = r_k^\ell - r_k^u$ per row/column, because sign defines the meaning.

Basic solutions in general

In general, any set of n linearly independent tight inequalities defines a unique solution, which can be computed by a **linear system of equations** $Bx = b$ with

- B an $n \times n$ submatrix of $\begin{pmatrix} A \\ I \end{pmatrix}$ corresponding to non-basic (tight) rows and columns,
- b the vector of bounds L_i, U_i, ℓ_k, u_k or 0 according to basis status.

In general, such a basis can be

1. **PRIMAL feasible** if $x = B^{-1}b$ satisfies all constraints
2. **OPTIMAL** if primal feasible and $c^T x$ minimal
3. **DUAL feasible** if ...?
4. **REGULAR** if none of the above
5. **SINGULAR** if $\text{rank}(B) < n$ (error, possibly due to numerics)

Basic solutions in general

In general, any set of n linearly independent tight inequalities defines a unique solution, which can be computed by a **linear system of equations** $Bx = b$ with

- B an $n \times n$ submatrix of $\begin{pmatrix} A \\ I \end{pmatrix}$ corresponding to non-basic (tight) rows and columns,
- b the vector of bounds L_i, U_i, ℓ_k, u_k or 0 according to basis status.

In general, such a basis can be

1. **PRIMAL feasible** if $x = B^{-1}b$ satisfies all constraints
2. **OPTIMAL** if primal feasible and $c^T x$ minimal
3. **DUAL feasible** if $B^T \gamma = c$ defines a dual solution y, r **with correct sign**
(patched by 0 for the basic (non-tight) rows/columns)
4. **REGULAR** if none of the above
5. **SINGULAR** if $\text{rank}(B) < n$ (error, possibly due to numerics)

Note: By this definition, basic solutions are complementary slack, so primal + dual = optimal!

Computational form

Most simplex solvers use a different form for their computations, introducing **slack variables** s :

$$\begin{array}{ll}\min & c^T x \\ \text{s.t.} & L \leq Ax \leq U \\ & \ell \leq x \leq u\end{array}$$

$\Leftrightarrow$

$$\begin{array}{ll}\min & c^T x \\ \text{s.t.} & Ax = s \\ & \ell \leq x \leq u \\ & L \leq s \leq U\end{array}$$

$\Leftrightarrow$

$$\begin{array}{ll}\min & c^T x \\ \text{s.t.} & Ax + s = b \\ & \ell \leq x \leq u \\ & b - U \leq s \leq b - L\end{array}$$

The feasible region is then embedded in an n -dimensional affine subspace of R^{n+m} and a basic solution is defined by **n variables fixed at lower or upper bound (or zero)**.

Redefining $A = (A, I)$, $x = (x, s)$ and $\ell = (\ell, L)$, $u = (u, U)$ gives the LP

$$\min c^T x \text{ s.t. } Ax = b, \ell \leq x \leq u$$

sometimes called standard form or **column representation** (vs. previous row representation).

Computational form

Most simplex solvers use the form $\min c^T x$ s.t. $Ax = b$, $\ell \leq x \leq u$ for their computations. Let

- $\mathcal{L}, \mathcal{U} \subseteq \{1, \dots, n + m\}$ be the index sets of nonbasic variables at lower/upper bound,
- $\mathcal{B} \subseteq \{1, \dots, n + m\}$ be the index set of (m) basic variables, and
- $B = A_{*,\mathcal{B}}$ be the $m \times m$ basis matrix,

then the values of the

- **basic variables** are given by $Bx_{\mathcal{B}} = b - A_{*,\mathcal{L}}\ell_{\mathcal{L}} - A_{*,\mathcal{U}}u_{\mathcal{U}}$,
- **dual multipliers** are given by $B^T y = c$.

Consequence:

- **primal feasibility** reduces to $\ell \leq x_{\mathcal{B}} \leq u$,
- **dual feasibility** reduces to $\bar{c}_k := c_k - y^T A_{*,k} \begin{cases} \leq 0 & \text{if } k \notin \mathcal{L}, \\ \geq 0 & \text{if } k \notin \mathcal{U}, \end{cases}$ for all k .

4. Primal and dual simplex

variants and tricks

5. Warmstarting and hotstarting

the simplex engine: LU factorization and updates

6. Beyond simplex

interior point and first-order methods

The primal simplex

Starting from a primal feasible basis $(\mathcal{L}, \mathcal{U}, \mathcal{B})$:

1. If dual feasible return optimal.
2. **Price**: choose violated non-basic column $k \notin \mathcal{B}$
3. **Ratio test**:
 - compute direction $d^k = B^{-1}A_{*,k}$ and step length $\hat{\delta} := \max\{\delta : \ell \leq x_{\mathcal{B}} - \delta d^k \leq u\}$
 - if $\hat{\delta} = \infty$ return unbounded, otherwise
 - choose basic variable $j \in \mathcal{B}$ for which $x_j - \delta d_j^k$ becomes tight
4. **Pivoting**: exchange k and i and update all data structures, continue.

The primal simplex

Starting from a primal feasible basis $(\mathcal{L}, \mathcal{U}, \mathcal{B})$:

1. If dual feasible return optimal.
2. **Price**: choose violated non-basic column $k \notin \mathcal{B}$
3. **Ratio test**:
 - compute direction $d^k = B^{-1}A_{*,k}$ and step length $\hat{\delta} := \max\{\delta : \ell \leq x_{\mathcal{B}} - \delta d^k \leq u\}$
 - if $\hat{\delta} = \infty$ return unbounded, otherwise
 - choose basic variable $j \in \mathcal{B}$ for which $x_j - \delta d_j^k$ becomes tight
4. **Pivoting**: exchange k and i and update all data structures, continue.

Obtain a starting basis by “**Phase I**”: the auxiliary LP

$$\min \sum z_i \text{ s.t. } Ax \pm z = b, \ell \leq x \leq u, z \geq 0$$

has a trivially primal feasible basis: x_k nonbasic, slack variables z_i basic with $\pm$ according to $\text{sign}(\bar{b} := b - A_{*,\mathcal{L}}\ell_{\mathcal{L}} - A_{*,\mathcal{U}}u_{\mathcal{U}})$.

More efficient: use slack variables s_i from column representation directly.

The dual simplex

Essentially performs the primal simplex on the dual LP, but has several advantages:

- **slack basis often dual feasible** (if lower and upper bounds finite)
- some linear algebra operations more efficient
- **bound flipping ratio test**: remember dual feasibility condition

$$\bar{c}_k := c_k - y^T A_{*,k} \begin{cases} \leq 0 & \text{if } k \notin \mathcal{L}, \\ \geq 0 & \text{if } k \notin \mathcal{U}, \end{cases}$$

When $\bar{c}_k$ becomes zero, one can often flip basis status and continue the step.

For more details, see Bob Bixby's CO@Work lectures:

<https://www.youtube.com/playlist?list=PLYWmzh0Y6E0YbrsKy1lyf9CSswLKkywY2>

Pricing strategies

The **textbook** rule (sometimes called “Dantzig” pricing):
choose k with max. reduced cost $|\bar{c}_k|$ over all violated columns.

This is **terrible**, because it ignores the direction d^k of the pivot.

Improvements:

1. **Exact steepest edge**: choose max. $|c^T d^k| / \|d^k\|$ (Goldfarb, Reid 1977)
 - need to initialize norms, but fast update available
2. **Devex**: cheaper, approximate steepest edge (Harris 1973)
3. **Quickstart steepest edge**: initialize norms with 1, update converges to steepest edge

Other tricks: partial pricing for LPs with many columns.

And a great talk by Sophie Huiberts on the contributions of **Paula Harris** to computational LP:
<https://www.youtube.com/watch?v=tb0ZvbpZp44>

Bound shifting and perturbation

A common problem:

- **primal degeneracy**: basic variables x_k at one of their bounds
- **dual degeneracy**: nonbasic reduced costs $\bar{c}_k = 0$

Both can lead to **zero step length** and **cycling** in primal/dual simplex.

Textbook solution (also known as Blands rule) **terrible**:
always price smallest violated index.

Bound shifting and perturbation

A common problem:

- **primal degeneracy**: basic variables x_k at one of their bounds
- **dual degeneracy**: nonbasic reduced costs $\bar{c}_k = 0$

Both can lead to **zero step length** and **cycling** in primal/dual simplex.

Textbook solution (also known as Blands rule) **terrible**:
always price smallest violated index.

Better: **bound shifting/perturbation**

- Add small random values to primal/dual bounds to break degeneracy
- the added violation is sometimes removed automatically later,
- or one can run phase 1.

Bound shifting and perturbation

A common problem:

- **primal degeneracy**: basic variables x_k at one of their bounds
- **dual degeneracy**: nonbasic reduced costs $\bar{c}_k = 0$

Both can lead to **zero step length** and **cycling** in primal/dual simplex.

Textbook solution (also known as Blands rule) **terrible**:
always pick smallest violated index.

Better: **bound shifting/perturbation**

- Add small random values to primal/dual bounds to break degeneracy
- the added violation is sometimes removed automatically later,
- or one can run phase 1.

Also used in the **Harris ratio test**: allow longer steps if it gives for numerically better pivots.

Composite simplex: interleaving primal and dual

Bound shifting can also be used to make a basis artificially feasible:

- **primal feasible**: by relaxing ℓ, u to include x_B
- **dual feasible**: by shifting c_k to make $\bar{c}_k = c_k - y^T A_{*,k}$ zero

This gives an **alternative to phase 1**:

- Choose a regular basis
- Shift objective to reach dual feasibility
- Run dual simplex to optimality
- Remove objective shift: preserves primal feasibility
- Run primal simplex to optimality

This is, e.g., the default strategy of SoPlex.

Can be started with the primal simplex, and interleaved.

- **change a right hand side / variable bound**: basis stays

Important in MIP: warmstarting after small changes

Suppose you have reached an optimal basic solution and you ...

- **change the objective**: basis stays primal feasible
→ warm-start primal simplex
- **add a column**: basis stays primal feasible if $\ell_k \leq 0 \leq u_k$ (add to nonbasic)
→ warm-start primal simplex
- **add a row**: basis stays dual feasible (add slack to basis)
→ warm-start dual simplex
- **change a right hand side / variable bound**: basis stays dual feasible
→ warm-start dual simplex

This makes the simplex a very efficient method in branch-and-cut and other algorithms where similar LPs need to be solved after small modifications.

In all cases the basis stays **regular** $\Rightarrow$ warm-starting always possible with phase 1/composite simplex, also if matrix coefficients change outside the basis matrix (but not always supported).

An experiment: warm-started dual simplex during tree search

depth	avg. iters

20	2.7
21	2.5
22	2.4
⋮	⋮

$383.7/3.3 \approx 116x$ speedup

Important in MIP: hotstarting after small changes

Suppose you have reached an optimal basic solution and you ...

- **change the objective**: basis stays primal feasible
→ hot-start primal simplex
- **add a column**: basis stays primal feasible if $\ell_k \leq 0 \leq u_k$ (add to nonbasic)
→ hot-start primal simplex
- **add a row**: basis stays dual feasible (add slack to basis)
→ warm-start dual simplex
- **change a right hand side / variable bound**: basis stays dual feasible
→ hot-start dual simplex

Hot-starting = reusing the (permuted) LU factorization $PBQ = LU$.

Row representation allows hot-starting after adding a row → favorable for branch-and-cut (and generally for LPs with many rows).

interior point and first-order methods

Alternatives to the simplex method

Computational challenges

- The simplex method parallelizes horribly (for all LPs).
- For some MIPs, the simplex takes much more iterations to reoptimize.
- For some MIPs, the root LP is the bottleneck.

Alternatives to the simplex method

Computational challenges

- The simplex method parallelizes horribly (for all LPs).
- For some MIPs, the simplex takes much more iterations to reoptimize.
- For some MIPs, the root LP is the bottleneck.

Interior point methods (a.k.a. barrier)

- parallelize very well, but do not warm start well:
- often combined with crossover to basic solution.

Alternatives to the simplex method

- The simplex method parallelizes horribly (for all LPs).
- For some MIPs, the simplex takes much more iterations to reoptimize.
- For some MIPs, the root LP is the bottleneck.

Interior point methods (a.k.a. barrier)

- parallelize very well, but do not warm start well:
- often combined with crossover to basic solution.

PDHG: Primal-dual hybrid gradient methods

- parallelize and warm-start beautifully (mostly matrix-vector multiply),
- but need many iterations (first-order method)
- and sometimes get stuck at lower precision.
- Growing amount of open-source GPU implementations available, e.g., cuPDLP-C
